Supporting Information

ABSTRACT: We study composites of cellulose nanocrystals (CNCs) in an ionomer matrix of poly(ethylene-*stat*-sodium acrylate) and find that direct cellulose/cellulose interactions in the composite are not a requirement for achieving reinforcement. While isotropic composites only show a slightly enhanced stiffness compared to the neat ionomer, a more substantial increase in Young's modulus by a factor of up to 5 is achieved by uniaxial alignment of the composites through melt spinning. The orientation of CNC in melt-spun composites reduces the probability of cellulose/cellulose interactions, which suggests that cellulose/polymer interactions must be present that lead to the observed reinforcement. Molecular dynamics simulations confirm strong cellulose/polymer interactions in the form of ionic interactions as well as hydrogen bonding. These cellulose/polymer interactions facilitate efficient stress transfer, leading to the high reinforcing effect of CNC, while cellulose/cellulose interactions play a minor role in the mechanical response of the composite.

INTRODUCTION

In the strive for mechanically strong and stiff materials, which are also lightweight and originate from renewable sources, cellulose fibers and their nanoscale derivatives receive widespread attention.^{1–5} Hydrolysis of refined cellulosic fibers liberates cellulose nanocrystals (CNCs), highly crystalline, elongated particles with a diameter of a few nanometers.⁶ The high stiffness in combination with its low density gives CNC a high specific modulus of about 90 MPa kg^{−1} m^{−3},⁷ which is comparable to the specific modulus of clay platelets.⁸ The critical challenge that must be met to utilize the full potential of CNC and other nanocelluloses in composites is to transfer the exceptional properties from a single cellulose crystal to the bulk nanocomposites. Knowledge about the mechanism of stress transfer is integral for the optimized utilization of nanocelluloses in composite materials. The two main modes of stress transfer that can occur in a CNC nanocomposite are (1) load sharing between the matrix and nanocellulose¹ and (2) the nanocellulose forms a load-bearing network governed by cellulose/cellulose contacts and transmission of force via the matrix plays a reduced role.^{9,10} The formation of a continuous network of a stiff reinforcing agent, such as CNC, will drastically increase the elastic modulus of a low modulus, rubbery polymer, which is well described in the cellulose literature.^{10–16}

A number of publications have highlighted the dilemma present in the manufacturing of cellulose nanocomposites:^{9,17–20} a homogenous dispersion and minimal aggregation of the nanocellulose demand favorable cellulose/polymer interactions, while formation of a percolated network of

cellulose requires favorable cellulose/cellulose interactions. Aitomäki and Oksman²¹ reviewed the reinforcing efficiency of nanocelluloses in numerous matrices and concluded that very few composites showed a mechanical response indicative of force transfer through the cellulose/cellulose contact. It has been argued⁹ that efforts to improve dispersion and decrease self-aggregation of nanocelluloses in nonpolar matrices by various surface treatments, such as surfactant adsorption,^{22,23} hydrophobization,^{23,24} or grafting of polymer chains,²⁵ also shield cellulose/cellulose interactions. Hence, cellulose cannot percolate, and the desired network is not formed. A high degree of surface modification decreases the strength of interaction between cellulose particles,²⁶ and therefore, any enhancement in stiffness, which has been observed in a number of composites,^{9,17–20,22,24,27} possibly occurred due to improved interactions between cellulose and the polymer matrix rather than the formation of a percolated cellulose network.

Here, we employ solvent casting of native CNC with a water-borne polymer latex of the ionomer poly(ethylene-*stat*-sodium acrylate) (EAA₁₅). The excellent dispersion attained using this water-based mixing technique^{10,11,28,29} makes such composites interesting systems to elucidate the mechanism of

stress transfer, i.e., to discern if forces are transmitted via a continuous cellulose network or if cellulose/polymer interactions are responsible for the reinforcing effect. Further, the EAA₁₅ polymer has a comparably high stiffness (235 MPa), relative to matrices in which cellulose networks have previously shown a strong reinforcing effect (typical polymer stiffness <10 MPa). Hence, the stress transfer behavior in the CNC/EAA₁₅ composite has interesting implications to judge the potential of reinforcement by a CNC network in other semicrystalline matrices. We carry out a detailed experimental investigation of a series of isotropic samples produced by water-assisted mixing, casting from the obtained suspension and subsequent compression molding. Further, we study anisotropic samples produced by melt spinning, where orientation of CNC reduces the number of possible cellulose/cellulose contacts. We conclude that the cellulose network present in the isotropic samples does not have a decisive impact on the composite modulus, but stress transfer via cellulose/polymer interactions has to be considered to explain the reinforcement in this type of cellulose nanocomposite. We also perform molecular dynamics (MD) simulations to gain detailed insight into the makeup of the cellulose/polymer interface and find a low-density polymer phase close to the CNC surface.

EXPERIMENTAL SECTION

Materials. NaOH-neutralized cellulose nanocrystals (CNCs) from sulfuric acid hydrolysis were obtained as a spray-dried powder from CelluForce, Canada. CNC was dispersed in water at a solid content of 4% using an Ultra Turrax high shear mixer at 14 000 rpm for 8 min. Poly(ethylene-*stat*-sodium acrylate), the NaOH-neutralized form of poly(ethylene-*stat*-acrylic acid) comprising 15 wt % acrylic acid (EAA₁₅), had a density of 0.994 g cm⁻³ and a melt flow rate of 36 g/10 min (ISO 1133, 190°/2.16 kg) and was obtained as an aqueous latex dispersion from BIMKemi AB, Sweden (20 wt % solid content; pH adjusted to 9.7 with NaOH).

Sample Preparation. CNC/EAA₁₅ composites were prepared by (1) mixing a freshly dispersed suspension of CNC with the EAA₁₅ dispersion using an excess of water (total water content 96 ± 1%), (2) vigorous stirring for 10 min, and (3) casting into polypropylene molds with subsequent drying at room temperature, which resulted in about 0.5 mm thick sheets with the desired CNC content. The dry composite sheets were milled in a rotor mill to obtain irregularly formed composite flakes, with sizes in the millimeter range. These flakes were pressed at 140 °C into plaques with a thickness of 500 μm. Unstretched extrudates were prepared by compounding the dried and milled composite material at 140 °C using a twin-screw Xplore Micro Compounder, followed by extrusion at a constant force (2–2.5 kN depending on sample viscosity) and take-up of the extrudates onto a treadmill, while fibers were prepared by collection of the extrudate with an Xplore Micro Fiber Line using three different collector speeds (0.1, 5, and 10 m min⁻¹) and a constant collector torque of 75 N. CNC films were prepared by casting a freshly dispersed suspension of CNC (4 wt % solid content) into polypropylene molds with subsequent drying at room temperature.

Extensional Rheology. Extensional rheology was performed using an Anton Paar MCR 702 TwinDrive rheometer equipped with an Anton Paar Universal Extensional Fixture at a temperature of 140 °C and Hencky strains of 0.1–20 s⁻¹. It should be noted that the ductility of samples prohibited sample fracture inside the rheometer; hence, the full range of strain hardening was not attained.

Differential Scanning Calorimetry (DSC). DSC was carried out under nitrogen between –50 and 150 °C at a scan rate of 10 °C min⁻¹ using a Mettler Toledo DSC2 calorimeter equipped with a HSS7 sensor and a TC-125MT intercooler. The sample weight was 3–4 mg. Fractional crystallization was carried out according to a previously published procedure,³⁰ i.e., annealing for 4 h at stepwise decreasing temperatures between 110 and 40 °C.

Transmission Electron Microscopy (TEM). Specimens for TEM were sectioned under cryo conditions using a Leica EM FC7 cryo ultramicrotome with a Diatome cryoknife at –120 °C. Sections (100 nm thin) were placed on formvar-coated copper grids, stained with uranyl acetate, and air dried at room temperature. Imaging was performed using an FEI Talos L120 TEM and recorded with a FEI Ceta CMOS 4k × 4k pixel detector.

Tensile Testing. Tensile testing was done with an Instron 5565A with a gauge length of 20 mm at a cross-head speed of 6 mm min⁻¹.

Dynamic Mechanical Analysis (DMA). DMA thermograms were recorded between –70 and 30 °C at a heating rate of 3 °C min⁻¹, a frequency of 20 Hz, and 0.1% strain using a Rheometrics Solids Analyzer RSA II. Prior to temperature sweeps, strain sweeps were carried out to ensure that the applied strain was within the linear viscoelastic region.

Thermogravimetric Analysis (TGA). TGA was carried out under nitrogen at a scan rate of 10 °C min⁻¹ using a Mettler Toledo TGA/DSC 3+.

Molecular Dynamics Simulations. All-atom molecular dynamics (MD) simulations were carried out with the OPLS-AA force field^{31,32} and the GROMACS v.2018 simulation package (see the Supporting Information for details).³³

Wide-Angle X-ray Scattering (WAXS). WAXS diffractograms were obtained using a Mat:Nordic instrument from SAXSLAB equipped with a Rigaku 003+ high brilliance microfocus Cu radiation source (wavelength = 1.5406 Å) and a Pilatus 300K detector placed about 43 mm from the sample.

Rotor-Synchronized Magic Angle Spinning (ROSMAS) Solid-State Nuclear Magnetic Resonance (NMR) Spectroscopy. NMR measurements were carried out using a Bruker 500 MHz Avance III, operating at 125.8 MHz for ¹³C. The ROSMAS experiment was conducted at ambient temperature and 1500 ± 1 Hz rotor rotation rate to sufficiently separate a few cellulose sidebands from other signals (see the Supporting Information for details).

RESULTS AND DISCUSSION

Preparation and Characterization of Isotropic CNC/EAA₁₅ Composites. As the matrix material, we selected the ionomer EAA₁₅ (Figure 1a), which has a polar comonomer

Figure 1. (a) Molecular structure of poly(ethylene-*stat*-sodium acrylate). (b) TEM image of a cryomicrotome-sectioned sample of a melt-pressed film of CNC/EAA₁₅ comprising 10.5 vol % CNC.

content of 15 wt %. EAA₁₅ is a branched polymer, as evidenced by extensional rheology (Figure S1), and features a statistical distribution of the polar comonomers, which are, on average, separated by 30 –CH₂– units (see Figure S2 for fractional crystallization of EAA₁₅). We prepared composites of EAA₁₅ with native CNC using water-assisted mixing, followed by casting from the obtained dilute water dispersion and finally compression molding of the dried and milled material into plaques. We note that the material did not experience any substantial shear during pressing, and therefore, we rule out

Figure 2. (a) Representative tensile stress–strain curves measured for neat EAA₁₅ as well as composites with 0.7–10.5 vol % and (b) Young's modulus E of isotropic composites (blue circles) as well as predicted moduli E_o predicted by the Halpin–Tsai model (dashed line) and Ouali model (solid line).

that this final preparation step influenced the distribution of the CNC reinforcing agent.

Transmission electron microscopy (TEM) images of cryo ultramicrotome cut thin sections of the obtained CNC/EAA₁₅ composite containing 10.5 vol % CNC show well-dispersed CNC (Figure 1b), comprising mainly individually dispersed CNC (length $L = (300 \pm 100)$ nm; diameter $d = (5 \pm 2)$ nm; cf. Figure S3) together with a minor fraction of aggregates. A comparison of different areas indicates that the degree of dispersion is comparable for different sections of the sample (Figure S4). The recorded TEM images reveal a good dispersion of CNC, which would allow the formation of a cellulose network. The percolation threshold, V_c , of rodlike nanoparticles is linked to the aspect ratio via¹

$$V_c = \frac{0.7}{L/d} \quad (1)$$

where L and d are the length and diameter of the nanoparticle, respectively. Eq 1 suggests that the here-used CNC, which has an aspect ratio of $L/d = 60$, can percolate above a volume fraction of 1.2 vol %.

Tensile Deformation of Isotropic Samples. We carried out tensile deformation experiments on specimens from isotropic, compression-molded composite films, having a CNC content of 0.7–10.5 vol % (Figure 2a; cf. the Supporting Information for calculation of vol %). We compared the change in Young's modulus E as a function of CNC content with values predicted by models that are commonly used to describe the behavior of cellulose nanocomposites (Figure 2b), keeping in mind the limitations of said models to correctly describe viscoelastic materials, as the theory behind them assumes completely elastic behavior of both matrix and reinforcement. We considered two models, the Halpin–Tsai and the Ouali model, which account for the geometry and elastic properties of the nanoscale reinforcing agent but differ in the way that interparticle interactions are treated. The former does not account for the stiffening effect from stress transfer via interparticle interactions, whereas the latter, which is a percolation model, considers interparticle interactions and their impact on the composite modulus.¹ According to the Halpin–Tsai model, E is given by³⁴

$$E = E_m \frac{(1 + \xi \eta V_r)}{(1 - \eta V_r)} \quad (2)$$

where

$$\eta = \frac{\frac{E_r}{E_m} - 1}{\frac{E_r}{E_m} + \xi} \quad (3)$$

where E_m and E_r refer to Young's modulus of the matrix and the reinforcing agent, respectively, and V_r and $\xi/2$ are the volume fraction and aspect ratio of the reinforcing agent. For the modulus of individual CNC particles, we used a literature value of $E_r = 130$ GPa, representing the average reported modulus for a single cellulose I crystal.⁵⁵ As such, the modulus predictions of the Halpin–Tsai model mark the upper bound for possible reinforcement, assuming perfect interfacial adhesion and dispersion, and using E_r of completely crystalline cellulose. Young's modulus of the matrix $E_m = 235$ MPa was measured by tensile deformation. Eq 2 can be extended to account for short fiber composites with randomly oriented fibers

$$E = E_m \left[A \frac{(1 + \xi_{\parallel} \eta_{\parallel} V_r)}{(1 - \eta_{\parallel} V_r)} + B \frac{(1 + \xi_{\perp} \eta_{\perp} V_r)}{(1 - \eta_{\perp} V_r)} \right] \quad (4)$$

where η_{\parallel} and η_{\perp} are calculated according to eq 3 with $\xi_{\parallel} = 2L/d$ and $\xi_{\perp} = 2$. A and B are coefficients related to the type of anisotropy. For composites that are isotropic in three dimensions, van Es³⁶ has proposed $A = 0.184$ and $B = 0.816$.

For the Ouali model, the composite elastic modulus is given by^{37,38}

$$E = \frac{(1 - 2\psi + \psi V_r) E_m E_n + (1 - V_r) \psi E_n^2}{(1 - V_r) E_n + (V_r - \psi) E_n} \quad (5)$$

In the adaptation of the Ouali model commonly used for cellulose nanocomposites,^{11,14} E_n is the elastic modulus of the reinforcing network, measured by tensile deformation of a neat CNC film. $E_n = 5.2$ GPa was measured by tensile deformation (see Experimental Section for details). ψ denotes the volume fraction of the reinforcing agent that participates in the percolating network and is obtained from

$$\psi = \begin{cases} 0 & V_f \leq V_c \\ V_r \left(\frac{V_r - V_c}{1 - V_c} \right)^b & V_f > V_c \end{cases} \quad (6)$$

where b is the critical percolation exponent, with a value of 0.4 in the case of a three-dimensional (3D) network,^{37,38} and V_c is taken from eq 1.

The trend of E with CNC content predicted by the Halpin–Tsai model for 3D isotropic composites (eq 4) is in good agreement with our experimental data up to a CNC content of 1.7 vol % (Figure 2b). At a higher CNC content, the predicted modulus is higher compared to the experimental values, which we explain with the onset of aggregation of CNC, bearing in mind that the Halpin–Tsai model assumes perfect dispersion of the reinforcing agent. In contrast, the Ouali model (eq 6) underestimates E at CNC concentrations of less than 1.7 vol %, while it shows a relatively good agreement with the experimental data at a higher CNC content. It is worth noting that, as the matrix is comparably stiff in comparison to the reinforcing network, the Ouali model predicts that the onset of percolation does not lead to a drastic increase in the modulus. Considering the relatively small difference between predictions of composite stiffness using the two models, we conclude that fitting models to mechanical data alone is not sufficient to judge the major path of stress transfer in our composites.

Melt Spinning of Anisotropic Composite Fibers. To gain additional insight into the relative importance of cellulose/cellulose and cellulose/polymer interactions in our CNC/EAA₁₅ composites, we prepared anisotropic, oriented fibers by melt spinning (Figure S5). Our aim was to create a set of samples with a high degree of uniaxial alignment of the CNC reinforcing agent, which reduces the probability of cellulose/cellulose interactions. This type of behavior has been observed for, e.g., oriented carbon nanotube composites, which display a drastic reduction in electrical conductivity due to loss of percolation.^{39,40} Carbon fiber composites show similar behavior, with an increase in percolation threshold due to orientation.⁴¹ Samples with a draw ratio of 1 were produced by extrusion and subsequent take-up of the extrudate onto a treadmill, without stretching, while fibers with draw ratios of 2–40 were prepared by extrusion and subsequent solid-state drawing.

CNC Orientation in Anisotropic Samples. To visualize the alignment of CNC, we prepared thin sections of anisotropic samples cut along the axis of orientation using a cryo ultramicrotome. TEM images of the CNC/EAA₁₅ composite with 10.5 vol % CNC reveal striking differences between isotropic material and anisotropic samples, in the form of unstretched extrudate and melt-spun fibers (Figure 3). The orientation of CNC occurs already upon extrusion and is further enhanced by the draw down experienced during melt spinning. Wide-angle X-ray scattering (WAXS; Figure S7) and solid-state nuclear magnetic resonance (solid-state NMR) spectroscopy in combination with the rotor-synchronized magic angle spinning (ROSMAS) technique^{42,43} confirm that CNC orients already upon extrusion and ROSMAS NMR further shows that alignment of EAA₁₅ requires solid-state drawing (Figures S8–S9).

The CNCs in the anisotropic samples display not only orientation but also an increased degree of aggregation with fewer individually dispersed CNC particles compared to the isotropic sample. It is worth noting that compounding, despite excellent dispersion preceding the melt processing step, can have adverse effects on CNC dispersion.^{9,44} Melt compounding has been reported to cause a reduction in the aspect ratio of nanocelluloses,^{45,46} to cause aggregation⁴⁷ and to have a severe impact on the microstructure resulting in a significantly reduced tensile modulus.⁴⁶ The here presented TEM images confirm that melt compounding of the composite impacts the dispersion of native CNC (Figure 3). We argue that

Figure 3. TEM micrographs of composites containing 10.5 vol % CNC with different levels of orientation; (a, b) isotropic composite prepared by compression molding of cast samples, (c, d) unstretched extrudate, and (e, f) fibers melt-spun at a draw ratio of 20. Images were postprocessed in Adobe Photoshop for contrast enhancement (see Figure S10 for original images).

mechanical shearing during melt compounding exposes the CNC to the hydrophobic bulk of the melt, composed of the ethylene segments of EAA₁₅, resulting in CNC aggregation. The CNC content, however, is not affected by melt processing as indicated by TGA thermograms of isotropic samples and melt-spun fibers with 10.5 vol % CNC, which indicate a comparable mass loss (Figure S11).

Tensile Deformation of Anisotropic Samples. Tensile deformation experiments reveal that the elastic modulus of anisotropic samples increases monotonically with both draw ratio and CNC content (Figure 4). Isotropic samples show a modest increase in modulus by a factor of up to 2 (Figure 2b). Instead, fibers of CNC/EAA₁₅ with 10.5 vol % CNC, prepared with a draw ratio of 20, display a substantial increase in E by almost 5 times (Figure S12), compared to drawn fibers of neat EAA₁₅. Evidently, despite the high degree of alignment, which reduces the probability of cellulose/cellulose interactions and hence prevents the formation of a percolating network, we continue to observe a reinforcing effect.

We again compared the increase in E as a function of CNC content with values predicted by the Halpin–Tsai model. We used a value of $E_m = 310$ MPa measured for a neat EAA₁₅ fiber with a draw ratio of 20 and treated the anisotropic samples as symmetric around 2 axes (eq 2). The Halpin–Tsai model for

Figure 4. Young's modulus E of samples melt-spun at draw ratios of 2, 10, and 20, along with isotropic samples, as a function of CNC volume content. Predicted moduli E_c by the Halpin–Tsai model for 3D isotropic composites (gray dashed line) and aligned composites, symmetric around 2 axes (black dotted line). $E_m = 235$ MPa for the 3D isotropic model while $E_m = 310$ MPa for the aligned model, which are the moduli of compression molded and stretched (draw ratio of 20) EAA₁₅, respectively.

aligned composites slightly overestimates the moduli measured for fibers prepared with a draw ratio of 20 (Figure 4), which we again explain with aggregation of CNC (Figure 3). The Halpin–Tsai model for aligned composites slightly overestimates the moduli measured for fibers prepared with a draw ratio of 20 (Figure 4). This is not surprising, keeping in mind that the aligned Halpin–Tsai model marks the upper bound for possible reinforcement, assuming perfect fiber alignment as well as perfect dispersion of reinforcement, both of which assumptions are not met in our composites (Figure 3). The Ouali model, in contrast, is not suitable to describe the oriented composite samples as percolation of CNC is thought to occur above the here-studied range of compositions. Provided that the CNC reinforcing agent does not form a percolating network, the reinforcing effect must instead occur due to stress transfer via cellulose/polymer interactions.

Cellulose/Polymer Interface Region. We used dynamic mechanical analysis to gain insight into the heterogeneity of the polymer matrix that may result from cellulose/polymer interactions. In particular, we extracted information about the glass transition temperature(s) T_g of neat EAA₁₅ and CNC/EAA₁₅ containing 10.5 vol % CNC (Figure 5). Neat EAA₁₅ shows a single peak in $\tan \delta$ at -42°C , whereas the composite feature two distinct peaks, located at -49 and -43°C . The emergence of a second T_g is reproducible in samples with lower cellulose loading (Figure S13). The occurrence of two distinct glass transitions suggests that two distinct types of domains exist within the polymer matrix, which we assign to bulk material and a polymer layer close to a CNC surface, respectively. The value of -43°C corresponds to the T_g of neat EAA₁₅, which indicates that part of the matrix material in the composite is comparable to neat EAA₁₅. The second peak in $\tan \delta$ at -49°C occurs at a lower temperature than the T_g of neat EAA₁₅. We argue that favorable interactions between EAA₁₅ and CNC change the nanostructure of EAA₁₅ close to the CNC surface (note that differential scanning calorimetry

Figure 5. (a) Storage and loss moduli E' and E'' and (b) loss tangent $\tan \delta$ of neat EAA₁₅ (black) and the composite with 10.5 vol % CNC (teal) measured with DMA; T_g values were extracted from peaks of the loss tangent $\tan \delta$.

(DSC) suggests a similar crystallinity of 11%; Figure S14). As a result, CNC particles are surrounded by a less dense EAA₁₅ phase where polymer chains can relax more easily compared to those located further away from the CNC surface, resulting in a lower T_g . This interpretation is consistent with the work by Venkatesh et al.²⁹ who used X-ray tomography to study composites of microfibrillated cellulose and EAA₁₅ and observed a lower density phase close to the surface of cellulose.

We used thermal gravimetric analysis (TGA) to compare the loss of volatiles such as water between 50 and 150 $^\circ\text{C}$ in neat EAA₁₅ and the composite containing 10.5 vol % CNC (Figure S15). The similar mass loss of 0.2–0.3% indicates that plasticization by water or other volatile species is unlikely to account for the presence of domains with a lower T_g .

Molecular Dynamics Simulations. We carried out molecular dynamics (MD) simulations at a temperature of 140 $^\circ\text{C}$, i.e., above $T_m = 90^\circ\text{C}$ of the matrix, to study the CNC/EAA₁₅ interface in more detail. In our simulations, EAA₁₅ was treated as a linear copolymer with sodium acrylate units statistically distributed along the chain, in line with the comonomer distribution inferred from fractional crystallization (Figure S2). We created 10 different linear chain models of EAA₁₅, each with a degree of polymerization (DP) of 64, which differed only in the positions of the carboxylate groups along the backbone. This oligomeric model of EAA₁₅ is here forth referred to as the ionomer. For CNC, a model of the I β allomorph of cellulose was created by arranging 5×5 cellulose chains in a cross-sectional rectangular shape, each chain having a DP of 20 (Figure S16). The primary surface hydroxyl groups of each chain were substituted with the sulfate half-ester groups, where seven out of ten groups were sulfonated, which corresponds to a typical experimental surface charge density of CNC corresponding to 200–335 $\mu\text{eq g}^{-1}$.⁴⁸ The sulfonate

groups carry a negative charge, and therefore, we introduce an additional 126 Na⁺ ions to neutralize the system.

MD Simulations: Nature of CNC/Ionomer Interactions. We calculated the radial distribution functions (RDFs) for various functional groups and ions to identify the main interactions between CNC and EAA₁₅. More specifically, we calculated RDFs between carboxylate groups (COO[−]) and sodium ions (Na⁺), between sulfonate groups (SO₃[−]) and Na⁺ (Figure 6a), between COO[−] groups, between COO[−] and SO₃[−] groups (Figure 6b), as well as between cellulose and the carbon atoms that make up the ionomer backbone (Figure 6c). It should be mentioned that for the carboxylate and sulfonate groups, we used the carbon and sulfur atoms, respectively, as reference points in the RDFs, e.g., the carboxylate–sulfonate group RDF is calculated between the C and S atoms. For the cellulose/polymer backbone RDF (Figure 6c), we used all atoms from cellulose as a reference.

The insets in Figure 6a–c show representative simulation snapshots and configurations highlighting the distances associated with the main RDF peaks. The Na⁺ cations are strongly coordinated with the COO[−] and SO₃[−] groups, which is evident from the peaks at around 3 Å (Figure 6a). The RDFs and simulation snapshot shown in Figure 6b demonstrate that there is strong coordination between COO[−] groups, as well as between COO[−] and SO₃[−] groups. These anionic groups would repel each other, and their interactions therefore must be mediated through Na⁺ ions. The cations are coordinated between two COO[−] or between COO[−] and SO₃[−] groups and thus form strong complexes due to electrostatic interactions. While the COO[−]–COO[−] bridges give rise to ionic clusters within the EAA₁₅, the COO[−]–SO₃[−] interactions result in adhesion of EAA₁₅ to the cellulose surface.

Further evidence for bridging of anionic groups by Na⁺ ions is given by the location of the RDF main peaks (Figure 6b). These peaks at about 5 Å are located at larger distances compared to the peaks in Figure 6a. This means that Na⁺ ions can be coordinated between two neighboring anionic groups, which was previously shown by density functional theory calculations.⁴⁹ Lastly, the RDF between the backbone carbon atoms of the ionomer and cellulose (Figure 6c) show that there is no preferential conformation of the polymer backbone with respect to the cellulose surface, as indicated by the absence of peaks in the RDF. This confirms that the main interactions between cellulose and the ionomer are between COO[−] and SO₃[−] groups mediated by Na⁺ ions. The absence of interactions between cellulose and the polymer backbone also implies that the good dispersion of CNC in our composites arises because EAA₁₅ has a relatively high amount of sodium carboxylate functional groups. CNC is known to aggregate in nonpolar matrices due to formation of hydrogen bonds between cellulose particles if there are no competing interactions favoring dispersion.^{35,50} Figure 6d clearly shows that some of the COO[−] groups (in red) are found next to the cellulose surface and extend into the polymer matrix, which prevents CNC aggregation.

MD Simulations: CNC/Ionomer Interactions Per Unit Volume. We used the results of our MD simulations to compare the nanostructure of the simulated CNC/ionomer composite and the neat ionomer. A comparison of simulation snapshots of these two systems (Figure 7a,b) reveals that the COO[−] groups together with Na⁺ form stringlike ionic aggregates that percolate through the ionomer matrix. Similar structures have been predicted by previous MD simulations of

ionomers.^{51–54} Figure 7c presents the number of clusters, normalized to the simulation box volume, of COO[−] groups bridged by Na⁺ ions as a function of the simulation time. Groups are identified to belong to the same cluster if the distance between them is less than 5.7 Å, which corresponds to the minimum in the RDF of two COO[−] groups after the first peak in Figure 6b. The simulated CNC/ionomer composite has almost double the amount of clusters per volume (~ 0.07 nm^{−3}) compared with the neat ionomer (~ 0.04 nm^{−3}). Additionally, the average number of COO[−] groups belonging to one cluster in the CNC/ionomer composite is 15.3 ± 0.2 , while clusters in the neat ionomer system comprise 24.8 ± 0.4 groups. These observations imply that the presence of cellulose in the polymer matrix disrupts the formation of ionic aggregates, and thus, more but smaller aggregates can be found in the CNC/ionomer composite. The tendency of the COO[−] groups to interact with the SO₃[−] groups, which was shown in the RDFs (Figure 6b), also indicates a competing interaction, which likely affects cluster formation.

We investigated the number of ionic bonds, formed via interactions between SO₃[−] from cellulose and COO[−] from the ionomer. The number of ionic contact points was normalized to the cellulose surface area. It should be noted that the cellulose surface area was calculated as the solvent-accessible surface area. Two groups are considered to be in contact if the distance between them is less than 7 Å, i.e., the minimum after the first peak in the RDF between SO₃[−] and COO[−] (Figure 6b). It should be noted that SO₃[−] can be in contact with more than one COO[−] group, which is evident from the inset snapshot in Figure 6b. The number of ionic contact points per surface area between SO₃[−] and COO[−] is found to be ≈ 0.63 nm^{−2} (Figure 7d).

We also considered the possibility for formation of hydrogen bonds between COO[−] groups of the ionomer (hydrogen-bond acceptors) and hydroxyl groups of cellulose (hydrogen-bond donors). The total number of available pairs is specified as the number of pairs of atoms able to form hydrogen bonds between CNC and the ionomer, which are within 3.5 Å distance from each other, normalized to the cellulose surface area. Of all of the available pairs able to form hydrogen bonds around 60% are bonded (Figure 7d). The total number of hydrogen bonds per unit cellulose area is ≈ 0.25 nm^{−2}. The presence of numerous hydrogen bonds, besides ionic bonds, further enhances the interaction between CNC and EAA₁₅.

Based on these findings we propose that the stress transfer in the here studied composite is mediated through a polymer layer, surrounding the CNC particles, which has a distinctly different nanostructure compared to the matrix further away from the CNC surface. MD simulations indicate that both the size and the number of ionic clusters are critically affected by the presence of CNC and that numerous ionic interactions as well as hydrogen bonding between CNC and the polymer take place. The emergence of a less dense polymer layer that surrounds CNC particles, consistent with the appearance of a second T_g' (cf. Figure 5), arises due to favorable interactions between EAA₁₅ and CNC.

CONCLUSIONS

We have studied a cellulose nanocomposite composed of CNC and an ethylene–acrylate ionomer matrix. Using a combined experimental and modeling approach, we have inferred the existence of a polymer layer close to the CNC surface where ionic clusters as well as hydrogen bonding govern the

interactions between CNC and EAA₁₅. We conclude that stress transfer in the composite is mediated via these strong cellulose/polymer interactions, and that cellulose/cellulose interactions play a minor role. The importance of cellulose/polymer interactions is confirmed by the five times higher storage modulus of melt-spun composite fibers, as compared to fibers of the neat matrix polymer since the orientation of CNC reduces the probability of cellulose/cellulose interactions.
